Abstract

We present an updated search for FCNC $D^0 \rightarrow \mu^+ \mu^-$ decays using 360 pb⁻¹ of Run II data. In addition to analyzing more data, the muon coverage is increased by also utilizing the CMX detector. The main source of background in the signal region is identified as coming from $B \rightarrow \mu^+ \mu^- X$ decays. A probability ratio is used to optimize the analysis by reducing the dominant background, while keeping the signal region blinded. The upgraded analysis sensitivity for setting a 90% credibility level is 6.5×10^{-7} , which is half the current best published limit of 1.3×10^{-6} .

The blind analysis expects a total of 8.7 ± 1.7 events, of which 4.9 ± 1.3 are expected in the CMU-CMU, 2.7 ± 1.0 in the CMU-CMX, and 1.0 ± 0.5 are expected in the CMX-CMX channels. After unblinding the data, 3 events are found in the CMU-CMU, no events in the CMU-CMX, and one event in the CMX-CMX channel. We use a Bayesian approach to extract the credibility level limits on the branching fraction that allows for the combination of several channels and the inclusion of nuisance parameters. We find $\mathcal{B}(D^0 \rightarrow \mu^+ \mu^-) < 5.3 \times 10^{-7}$ at the 95% credibility level and $\mathcal{B}(D^0 \rightarrow \mu^+ \mu^-) < 4.3 \times 10^{-7}$ at the 90% credibility level.

1 Introduction

In the Standard Model, the flavor-changing neutral current decay $D^0 \rightarrow \mu^+\mu^-$ is suppressed by the GIM mechanism. Figure 1 shows some of the basic Feynman diagrams contributing to $D^0 \rightarrow \mu^+\mu^-$ decays in the Standard Model. The decay rate is dominated by long-range contributions [1], in particular the diagram shown in Figure 2. The total Standard Model branching fraction is estimated [1] to be $\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) \geq 4 \times 10^{-13}$.

Figure 1: A few of the possible Feynman diagrams for the $D^0 \rightarrow \mu^+\mu^-$ decay in the Standard Model.

Figure 2: The dominant long-distance Feynman diagram for the $D^0 \rightarrow \mu^+\mu^-$ decay in the Standard Model

As opposed to $B_s^0 \rightarrow \mu^+\mu^-$, which is enhanced in SUSY models by $\tan\beta$ terms due to couplings with down-type quarks, virtually no enhancement of this decay is expected from the canonical, \mathcal{R} -parity conserving SUSY models. However, in \mathcal{R} -parity violating SUSY models, enhancements are possible. Reference [1] takes into account other restrictions on \mathcal{R} parity violation and estimates that enhancements of the D^0 branching fraction up to 3.5×10^{-6} . This leaves seven orders of magnitude of the D^0 branching fraction to be probed for new physics effects. The current best experimental limit on the $D^0 \rightarrow \mu^+\mu^-$ -branching fraction comes from BaBar [2], and is equal to:

$$\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) \leq 1.3 \times 10^{-6} \quad (1)$$

at the 90% C.L. CDF has already performed a search for these rare decays using the first 60 pb^{-1} of Run II data, and set a limit of $\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) \leq 2.5 \times 10^{-6}$ [5]. This study builds on the experience of the previous measurement adding more data, using a muon identification

likelihood developed for the B_s -mixing analysis, utilizing an additional detector component to increase the coverage of muon identification, and incorporating a more detailed analysis of background sources.

Figure 3: An \mathcal{R} -parity violating SUSY $D^0 \rightarrow \mu^+\mu^-$ decay process, a possible tree level contribution.

2 Measurement Technique

The strategy of the measurement is rather simple, and follows the same strategy of the previous measurement [5]. Charged, two-body D^0 decays are gathered with the two-track trigger; minimal additional track quality requirements are imposed. The combinatorial backgrounds are vastly reduced by requiring a $D^{*-} \rightarrow D^0\pi^-$ tag. We demand that the mass difference between the D^{*-} and D^0 candidates fall between 0.144 and 0.147 GeV/c. Figure 4 illustrates the size of the charm sample selected with this technique in the $D^0 \rightarrow K^+\pi^-$ -channel, and the power of the D^* requirement to reduce the background. The resulting $D^0 \rightarrow K^+\pi^-$ -sample of 900,000 decays is used to determine characteristics of the $D^0 \rightarrow \mu^+\mu^-$ -signal.

The two-track candidates are reconstructed a $\mu^+\mu^-$ mass hypothesis, and the D^{*-} tag mass-difference cut is applied. The mass distributions of the selected events are displayed in Fig. 5. We classify the events according to the muon detector subsystem the tracks intercept, central (CMU) or extension (CMX). Considering both tracks of the D^0 candidate, three cases occur: when both tracks fall in the acceptance of the central muon system the event is classified as CMU-CMU; when both tracks fall in the acceptance of the extension muon system the event is classified as CMX-CMX; and when one track falls in each the event is classified CMU-CMX.

The invariant mass of the track pair is required to fall inside a search window. Using background subtraction, the number of $D^0 \rightarrow \mu^+\mu^-$ -decays in the search window is determined. The $D^0 \rightarrow \pi^+\pi^-$ -peak is used as a reference signal to determine the branching fraction:

$$\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) = \frac{N(\mu^+\mu^-)}{N(\pi^+\pi^-)} \cdot \frac{\epsilon(\pi^+\pi^-)}{\epsilon(\mu^+\mu^-)} \cdot \mathcal{B}(D^0 \rightarrow \pi^+\pi^-), \quad (2)$$

where $N(\mu^+\mu^-)$ is the number of observed dimuon decays, $N(\pi^+\pi^-)$ is the observed number of reference decays, $\epsilon(\pi^+\pi^-)/\epsilon(\mu^+\mu^-)$ is the relative efficiency for triggering and reconstructing

Figure 4: The $D^0 \rightarrow K^+\pi^-\pi^-$ reference sample selected with the same basic requirements applied to select the signal. The left plot shows the mass distribution before the D^* requirement. The middle plot shows the difference between the $K\pi\pi$ mass and the $K\pi$ mass used to apply the D^* requirement. And the right plot shows the result of selecting only those decays with a mass difference between 0.144 and 0.147 GeV/c .

Figure 5: The $\mu^+\mu^-$ mass distributions of events satisfying the basic event selection requirements for CMU-CMU (left), CMU-CMX (middle), and CMX-CMX (right) candidates. The dashed lines indicate the search region for $D^0 \rightarrow \mu^+\mu^-$ events. The kinematically similar $D^0 \rightarrow \pi^+\pi^-\pi^-$ events produce the peak overlapping the search region. These events are used to normalize the $D^0 \rightarrow \mu^+\mu^-$ measurement, but are also a potential source of background when both pions are misidentified as muons.

$\pi^+\pi^-$ and $\mu^+\mu^-$ decays, respectively, and $\mathcal{B}(D^0 \rightarrow \pi^+\pi^-) = (1.364 \pm 0.032) \times 10^{-3}$ [3] is the reference branching fraction for $D^0 \rightarrow \pi^+\pi^-$ decays.

But $D^0 \rightarrow \pi^+\pi^-$ decays can also fake the $D^0 \rightarrow \mu^+\mu^-$ signal if both pions are misidentified as muons. To minimize the misidentification probability we utilize a likelihood function for muon identification that takes into account dE/dx information from the tracker, and electromagnetic and hadronic calorimeter energy deposition, as well as muon detector information. The likelihood function achieves high efficiency while providing additional suppression for hadrons. The probabilities for pions and kaons to be misidentified as muons is estimated from the D^* tagged $D^0 \rightarrow K^+\pi^-$ data. The results are displayed in Figs. 6–9 as functions of track transverse momentum p_T , pseudorapidity η , and azimuthal angle ϕ .

Figure 6: The muon misidentification probabilities for pions in the central muon system as functions of track transverse momentum p_T (left), pseudorapidity η (middle), and azimuthal angle ϕ (right). Positive (red) and negative (blue) pions are shown separately as a cross-check.

Figure 7: The muon misidentification probabilities for kaons in the central muon system as functions of track transverse momentum p_T (left), pseudorapidity η (middle), and azimuthal angle ϕ (right). Positive (red) and negative (blue) kaons are shown separately as a cross-check.

Different decay processes can mimic $D^0 \rightarrow \mu^+\mu^-$ decays. The dominant background before muon identification are $D^0 \rightarrow \pi^+\pi^-$ decays. In addition we consider backgrounds arising from:

Figure 8: The muon misidentification probabilities for pions in the extension muon system as functions of track transverse momentum p_T (left), pseudorapidity η (middle), and azimuthal angle ϕ (right). Positive (red) and negative (blue) pions are shown separately as a cross-check.

Figure 9: The muon misidentification probabilities for kaons in the extension muon system as functions of track transverse momentum p_T (left), pseudorapidity η (middle), and azimuthal angle ϕ (right). Positive (red) and negative (blue) kaons are shown separately as a cross-check.

misidentified $D^0 \rightarrow K^+\pi^-$ decays; D^* tagged semimuonic D^0 decays with a hadronic track misidentified as a muon; semimuonic b hadron decays with a hadronic track misidentified as a muon; $B \rightarrow \mu^+\mu^-X$ decays arising primarily from cascade semimuonic decays of the b hadron and c hadron; combinatorial background with two misidentified hadrons. Figure fig:bmumu illustrates the sources of background from b hadron decays before muon identification is required, along with the misidentification fractions for the primary contributors.

Figure 10: Background sources from B decays.

We find that the main background in our search is due to $B \rightarrow \mu^+\mu^-X$ decays. The measurement is optimized by rejecting the dominant background using a probability ratio discriminating prompt charm from b hadron decays using the impact parameter and displacement significance of the two-track system. Figure 11 demonstrates the discriminating power of these quantities. We find that roughly 85% of the signal can be retained while rejecting about 60% of the dominant background.

Table 1 lists the background contributions to the search window found for each source. The backgrounds are determined separately for each channel. The dominant source is still $B \rightarrow \mu^+\mu^-X$ decays. The total background is estimated from the sum in quadrature of all the contributions, where contributions listed as an upper limit are added to the error on the mean, but not the mean itself.

3 Sensitivity and Limits

The interpretation of the measurement is contained in the following equation:

$$\mathcal{B}(D^0 \rightarrow \mu\mu) = \frac{N(\mu\mu)}{N(\pi\pi)} \cdot \frac{\epsilon(\pi\pi)}{\epsilon(\mu\mu)} \cdot \mathcal{B}(D^0 \rightarrow \pi\pi) \quad (3)$$

Figure 11: Quantities used to separate prompt charm meson decays from background due to B decays.

Table 1: Background contributions for the optimized analysis selection. Contributions from different sources are summed in quadrature to yield the total estimate. The final row is the number of observed decays in the search window for each channel.

Source	CMU-CMU	CMU-CMX	CMX-CMX
Combinatorial Background	0.040 ± 0.007	0.008 ± 0.001	0.0007 ± 0.0001
$D^0 \rightarrow \pi\pi$ double fakes	0.53 ± 0.005	0.057 ± 0.001	0.012 ± 0.002
$D^0 \rightarrow K\pi$ double fakes	< 0.01	< 0.01	< 0.01
Semimuonic D^0 decays	< 0.36	< 0.20	< 0.10
Semimuonic B Decays	0.54 ± 0.06	0.13 ± 0.03	0.07 ± 0.02
Cascade semimuonic B decays	3.8 ± 1.3	2.5 ± 1.0	1.0 ± 0.5
Total	4.9 ± 1.3	2.7 ± 1.0	1.0 ± 0.5
N_{obs}	3	0	1

where $N(\mu\mu)$ is the observed number of $D^0 \rightarrow \mu\mu$ decays in the search window, $N(\pi\pi)$ is number of reference $D^0 \rightarrow \pi\pi$ decays, $\epsilon(\mu\mu)$ and $\epsilon(\pi\pi)$ are the efficiencies for accepting di-muon and di-pion decays, respectively, and $\mathcal{B}(D^0 \rightarrow \pi\pi)$ is the branching fraction for the reference $D^0 \rightarrow \pi\pi$ decay. The number of observed $D^0 \rightarrow \mu\mu$ decays is calculated by subtracting the number of expected decays due to background processes, N_{bkg} from the number of observed decays in the search window, N_{obs} :

$$N(\mu\mu) = N_{\text{obs}} - N_{\text{bkg}}. \quad (4)$$

If a significant excess of observed decays over expected decays is found, the interpretation of the result is trivial. The number of $D^0 \rightarrow \mu\mu$ decays is calculated from Eq. 4, and the observed branching fraction is calculated from Eq. 3.

The question is slightly more complicated in the case of setting limits, mostly because a lot of the inputs to Eqs. 3 and 4 have uncertainties. For instance, the efficiencies $\epsilon(\mu^+\mu^-)$, $\epsilon(\pi\pi)$, the number of expected decays N_{bkg} are all measured quantities with associated uncertainties which have to be taken into account when setting limits. Obviously, one also wants to combine the results obtained in the three channels: CMU-CMU, CMU-CMX and CMX-CMX. We use a Bayesian approach to setting limits on $\mathcal{B}(D^0 \rightarrow \mu^+\mu^-)$ that allows for the combination of a number of channels and the inclusion of uncertainties on input quantities (nuisance parameters) [7].

The sensitivity of the measurement was estimated before opening the box, using the estimated efficiencies and backgrounds, and assuming zero signal. We generate 1000 “toy experiments”, each with a number of events observed randomly generated according to a poisson distribution with mean equal to the expected background.

The limit on the branching ratio is calculated for each experiment at the 90%, and 95% credibility level. The distributions of limits are displayed in Figs. 12–13. The median of the distribution of limits is quoted as the sensitivity of the measurement. The sensitivities are 6.5×10^{-7} at the 90% credibility level, and 7.8×10^{-7} at the 95% credibility level.

We count the number of events found in the signal mass window, shown in Fig. 14. We find three candidates in the CMU-CMU channel, none in the CMU-CMX channel and one candidate in the CMX-CMX channel, listed in the last row of Table 1. These observations are consistent with expected background, so we will quote a limit on the branching fraction.

The resulting limit is

$$\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) < 0.43 \times 10^{-6} \text{ at the 90\% CL}$$

and

$$\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) < 0.53 \times 10^{-6} \text{ at the 95\% CL.}$$

The probability for these limits, assuming there is really no signal, is about 15% and is indicated in Figs. 12 and 13.

4 Conclusions

We have presented an update of the search for FCNC $D^0 \rightarrow \mu^+\mu^-$ decays using 360 pb⁻¹ of Run II data. The analysis has been expanded to also include muons in the fiducial region

Figure 12: The distribution of limits at the 90% confidence level obtained for 1000 toy experiments. The median of the distribution is indicated by the green arrow. The red shaded area indicates those results equal to or less than the result obtained for our data.

Figure 13: The distribution of limits at the 95% confidence level obtained for 1000 toy experiments. The median of the distribution is indicated by the green arrow. The red shaded area indicates those results equal to or less than the result obtained for our data.

Figure 14: Mass distributions for double-tagged decays in different subdetector configurations. The blue points are the measured event counts in data. The different overlaid distributions are contributions from different background sources. The distributions are stacked on top of each other.

of the CMX detector. The increased sample size allows for a more detailed study of the dominant background, resulting in a first identification of $B \rightarrow \mu\mu X$ decays as being the most likely physics source of background in the signal mass range. Using a likelihood ratio function, we reject about half of the dominant background while keeping almost 85% of the signal. After looking at events in the signal region, we find 3 CMU-CMU, 0 CMU-CMX and 1 CMX-CMX candidates. We set the following limits on the branching ratio of the D^0 decay: $\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) < 4.3 \times 10^{-7}$ at the 90% CL, and $\mathcal{B}(D^0 \rightarrow \mu^+\mu^-) < 5.3 \times 10^{-7}$ at the 95% CL. This is roughly a factor of three better than the best published result [2], and an improvement of roughly a factor of five with respect to the previous CDF analysis [5].
